ABSTRACT

Aim: The aim of this study was to evaluate the effect of pilocarpine on the histological changes, induced by exposure to radiation therapy, in the rat’s lingual salivary glands. Subjects and methods: This study was carried on 30 adult male Sprague-Dawley rats weighing 150-250 g. That the rats were divided into 3 groups (10 rats per each). Group I: Control group received neither radiation nor drug. Group II: exposed to a single whole body γ-irradiation at dose of 6 Gray (Gy). Group (3): the rats were injected intraperitoneally by a single dose of pilocarpine hydrochloride (0.2 mg/kg) 90 minute before the exposure of the previous dose of radiation. Results: One week after x-ray radiation the glands demonstrated marked destructive changes. These changes comprise in the form of loss of acinar architecture, and acinar degeneration and atrophy. Pilocarpine administration prior to radiation has decreased, but not completely prevents, the harmful effects of radiation. The radioprotective effect of pilocarpine treatment was manifested by the decreased atrophic changes and the absence of degenerated acinar cells. Conclusion: Administration of pilocarpine can protect, to some extent, the lingual salivary glands against radiation histological damage.

INTRODUCTION

Head and neck cancer is the sixth most common malignancy worldwide. Each year about 500,000 patients world-wide were treated for head and neck cancer. The majority of these patients were treated with radiotherapy either alone or in combination with other treatment modalities such as surgery and/or chemotherapy. Radiation therapy has been used effectively in treating head and neck cancers for many decades; it is used to cure cancer and also to alleviate cancer-associated symptoms. The use of radiation as a therapeutic measure leads to significant alterations that occurs not only in cancer cells but also in healthy tissues. It causes also unwanted symptoms during and after the treatment, including dry mouth or xerostomia, mucusitis, dental carries, difficulty in swallowing, and eventually inadequate...
feeding. Therefore, xerostomia significantly impairs patients’ quality of life and can compromise the continuity of their cancer treatment. Several studies have shown significant improvement in radiation induced xerostomia when pilocarpine was given along with radiotherapy.

Pilocarpine pretreatment was also proved as protective agent against irradiation, displaying much less damage after irradiation of the same dosage.

Pilocarpine is a naturally occurring compound derived from the South American shrub *Pilocarpus jaborandi*. This plant alkaloid is a cholinergic parasympathomimetic agonist that binds to muscarinic-M3 receptors and can cause pharmacological smooth muscle contraction in humans and stimulation of various exocrine glands. Pilocarpine hydrochloride (Salagen) are currently indicated for treatment of radiation-induced dry mouth.

In a previous study use of pilocarpine provided significant relief to patients with radiation-induced dry mouth. They demonstrated that, the use of pilocarpine significantly improved symptoms of intraoral dryness, oral discomfort, and dysphonia and patients’ global assessment of dry mouth as well as reduced the need for administration of oral comfort agents such as artificial saliva, water, and hard candy. The patients also demonstrated a statistically significant increase in saliva production, measured as either whole-mouth or parotid salivary flow. It is through this mechanism that cholinergic stimulation of residual-functioning exocrine glandular tissue in patients There have been many animal studies on the effect of radiation on the major salivary glands, however no studies reported in regard to the effect of radiation on the lingual salivary glands. The aim of this study was to evaluate the histological alterations that occur in the lingual salivary glands acinar cells of rats subjected to radiation with or without pilocarpine pretreatment.

**MATERIALS AND METHODS**

**Experimental animals:**

30 adult male Sprague-Dawley rats weighing 150-250 g were used in this investigation. The procedure and management were carried out at the animal house of National Center of Radiation Research and Technology (NCRRT), Cairo, Egypt.

The experiment was performed after accommodation period in the laboratory environment for 7 days. The rats were housed in a room with controlled temperature 25°C ± 2°C, humidity 50% ± 5%, and about 12-hour light/dark cycle and were fed on chew and water ad libitum.

**Grouping and drug administration:**

The animals were divided randomly into 3 main groups as follows:

- **Group (1):** the control group consisted of 10 rats used as control for the other group of animals, and received neither radiation nor drug.

- **Group (2):** consisted of 10 rats will be exposed to a single whole body γ-irradiation at dose of 6 Gray (Gy).

- **Group (3):** consisted of 10 rats injected intraperitoneal by a single dose of pilocarpin (0.2 mg/kg) (Sigma Chemical Co., St. Louis, MO) dissolved in 1ml of normal saline then exposed to a single whole body γ-irradiation at dose of 6 Gray (Gy).

**Irradiation Technique:**

The whole body irradiation of animals was performed at National Center of Radiation Research and Technology (NCRRT), Cairo, Egypt, using Gamma cell 40. Gamma cell 40 is a Cesium 137 irradiation unit manufactured by Atomic Energy of Canada Limited (AECL) and designed for use in an unshielded room. The unit provides a mean for a uniform gamma irradiation of small animals or biological samples while providing adequate ventilation for experimental animals and complete protection for operating personnel.
The Cesium 137 source provides a dose rate of 6 Gy/min.

For the study of the lingual salivary glands, the root of the tongue were processed microtechnically, embedded in paraffin wax and the sections were cut at 5-7 μm thick and prepared for staining with hematoxylin and eosin stain.

RESULTS

Group (I): the control group (no-irradiation)

A) Von-Ebner’s gland is a serous gland, located under the circumvallate papillae in the lamina propria of the tongue and extend deeply in the submucosa until reach to the muscular layers. Their ducts open at the bottom of the groove surrounding the circumvallate papillae. The lobules were seen separated from each other by muscles bundle, adipose tissue and little amount of loose connective tissue which rich in blood vessels and nerve fibers. The lobules consist of densely packed acini cells, lined by pyramidal cells. The serous acini cells have a rose shape with narrow lumen, stained darkly with (H&E) stain from pink to purple (Fig 1, A)

B) The Weber’s gland is a mucous gland, found in the root of the tongue. The glands have a variable number of lobules which present within lamina propria as well as extending to the muscular layer and open in the epithelial surface of the tongue in the root region, some of lobules located deeply to Von Ebner’s glands in the muscular layer. The lobules are different in size and shape, supported by a loose connective tissue which contains collagen fibers, blood vessels, nerve fibers, and adipose tissue separating between the lobules. Each lobule consists from densely packed mucous acini lined by relatively large pyramidal cells and has small round nuclei located at the base of cell near the basement membrane. A small lumen seen in the center of acini.

Fig. (1B) Photomicrograph of Weber’s gland showing variable number of glandular lobule which extend between the tongue muscles. Each lobule consist from densely packed mucous acini. (H&E stain x100)

Group (II): (rats exposed to a single dose of irradiation)

(A&B) The serous acini of Von-Ebner’s gland was the most affected cells by radiation. The radiation provoked many destructive changes in the glands. These changes comprise loss of normal architecture, acinar atrophy, acinar degeneration and deeply-stained variable-sized nuclei. The acinar atrophy was manifested in the gland in the form of increased interacinar spaces. The acinar degeneration was represented as empty spaces in the acinar lobules. Some areas of the tongue noted with dilatation.
ed blood vessels. Extravasated red blood cells also seen. Marked inflammatory cell infiltration were also noted (Fig. 2,A&B).

(C&D) The mucous acini of the Weber gland appeared more resistant to the degenerative changes of exposure to radiation. However, some acinar cells revealed areas of degeneration, marked enlargement of the acini and loss of normal architecture. The nucleus of the acinar cell appeared displaced basally. (Fig 2, C&D).

**Group (III):** rats injected with a single dose of pilocarpine and then exposed to a single whole body γ-irradiation at dose of 6 Gray (Gy):-

(A) The serous acini of Von-Ebner’s gland demonstrated mild acinar degeneration and the acinar architecture was slightly altered. The nuclei of acinar cells were deeply stained. Fig (3,A).

(B) The mucous acini of the Weber gland demonstrated slight enlargement. The gland demonstrated intact acinar architecture with neither acinar atrophy nor acinar degeneration. Fig (3,B).

---

Fig. (2) (A&B) the Von-Ebner’s gland showing severe acinar atrophy and acinar degeneration with empty spaces in the acinar lobules due to loss of some acini, remnant of degenerated acinar cells and marked inflammatory cell infiltration. Dilated blood vessels containing RBCs and extravasated red blood cells also seen (H&E x200).

The radioprotective effect of many materials against salivary glands dysfunction were studied. In this study we try to observe the radioprotective effect of pilocarpine on the lingual salivary glands of the rats. The present study demonstrated many degenerative changes in the lingual salivary glands when they are exposed to radiation.

The secretory granules content of the serous cells in the Von-Ebner’s gland in the present study were reduced by radiation. Similar results were also reported in the granular convoluted tubules of the submandibular gland by Vissink et al., (1991) (12).

The radiation has induced destructive changes in the investigated salivary glands, which are demonstrated in the form of massive injuries of both the acinar and ductal architecture as the acinar atrophy, intracytoplasmic vacuolation and degeneration with nuclear changes including the pleomorphism and hyperchromatism. These findings were comparable with those reported in the previous studies among. (13)

The observed atrophic changes of serous acini in the Von Ebner gland were also documented on the parotid and the submaxillary glands by Ahlner et al. (14).

The early response resulting in the atrophic changes of the secretory cells, without inflammation were presumed to be due to radiation-induced apoptosis, while the late response with inflammation could be the result of radiation-induced necrosis. (15) Other investigators, however, have proposed that the progressive loss of acini in the parotid and submandibular glands can be correlated to the activation of mast cells and the release of their secretory products. (16)

In the present study, the serous acinar cells were demonstrated to be highly sensitive to irradiation and these results are consistent with those observed by Nagler (17) in the submandibular and sublingual salivary glands of rats.

The mechanism by which this occurs is controversial and not clear however, it has been suggested that the serous secretory granules have proteolytic and metallic transmission enzymes. The transmission materials are known to promote the formation of the free radicals, thereby, potentiating the damage to the serous granule membranes. As a result, the proteolytic enzymes may infiltrate and damage the cytoplasm, causing autolysis and cellular death. (164)

The improved salivary gland function has been observed in rats when degranulation was stimulated.

Fig. (3,A) Photomicrograph of group III showing mild acinar degeneration and the acinar architecture was slightly altered. (B) The mucous acini of the Weber gland demonstrated slight enlargement. H&E stain x200.
by pilocarpine administration prior to the radiation exposure.\(^{(17)}\) The involvement of the serous secretory granules associates with the increased damage caused by ionizing radiation was further confirmed by \((18,19).\)

In the present study, the pilocarpine administration prior to radiation have decreased the harmful effects of radiation. However, the administration of pilocarpine not completely prevent all the radiation-induced pathological alterations. The radioprotective effect of pilocarpine treatment was manifested by the decreased atrophic changes and the absence of degenerated acinar cells.

The salivary glands have been suggested to have dual innervation, the parasympathectomy which prevents the attainment of the adult gland size, the normal proliferation and the DNA and RNA content, while the sympathectomy has only moderate influence on the cells and gland size.\(^{(20)}\)

The pilocarpine hydrochloride is known as a cholinergic parasympathomimetic agent exerting a broad spectrum of pharmacologic effect with predominant muscarinic action and in appropriate dosage it can increase the secretion of exocrine glands.\(^{(21)}\)

Greenspan and Daniels\(^{(22)}\) observed expulsion of secretory granules from the serous cells in exocrine fashion by pilocarpine. The pilocarpine, a parasympathetic agonist, has been found to effectively stimulate salivation of the rat 30 to 60 minutes after injection.\(^{(23)}\) Histologically, the pilocarpine has been proven to cause moderate depletion of granules. Whereas the atropine increased the amount of granules. The results showed that the salivary glands in pilocarpine-pretreated group of animals was less damaged by irradiation than those without pilocarpine treatment.

histological evaluation of the effect of pilocarpine on the lingual salivary glands of the root of the tongue after x-ray irradiation in rats

hesham a. dameer, et al.

the purpose of this study was to investigate the effect of pilocarpine on the lingual salivary glands of the root of the tongue in rats after exposure to x-ray.

the study utilized histological examination. the study was conducted as follows: 30 male rats were divided into three equal groups. the first group was the control group and consisted of 10 rats that were not exposed to radiation. the second group was exposed to radiation alone at a dose of 250 mg.

the third group received pilocarpine in the form of tablets until they absorbed the pill. the second group was exposed to radiation at the same dose used in the first group. then, the tongue was extracted and the root of the tongue was cut and the samples were collected immediately for hematoxylin and eosin staining to perform a histological examination in 72 hours in calcium formaldehyde solution.

the results showed that the glands suffered from severe damage after exposure to radiation. these changes were in terms of loss of glandular structure, atrophy and shrinking of the salivary glands, and decreased pilocarpine intake before radiation, but not completely. the harmful effects of radiation were manifested through atrophy and lack of the atrophic cells in the salivary glands.

the study concluded that pilocarpine was effective in protecting the salivary glands after exposure to radiation.

the keywords: radiation, pilocarpine, lingual salivary glands, aging, atrophic cells.
